# Why Do We Care About Predictions?

- Everyone cares about the prediction of macro economic/political/natural outcomes.
  - · Population, elections, GDP, poverty, tax policy, market research, when will humans run out of fossil fuel, etc.
- Sometimes good predictions could directly lead to good decisions/policies.
  - Weather forecast, demand forecast, stock/asset return, recommendation system, user/patient LT(V), cancer screening, insurances, bail out, etc.

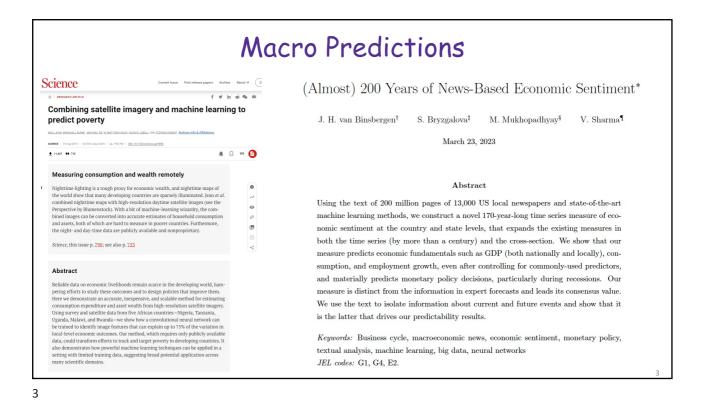

$$\frac{d\pi(X_0, Y)}{dX_0} = \frac{\partial \pi}{\partial X_0} \underbrace{(Y)}_{\text{prediction}} + \frac{\partial \pi}{\partial Y} \underbrace{\frac{\partial Y}{\partial X_0}}_{\text{causation}}.$$

Prediction Policy Problems

By Jon Kleinberg, Jens Ludwig, Sendhil Mullainathan, and Ziad Obermeyer  $^{\textcircled{\$}}$ 

- · Causal inference is all about predicting the counterfactual outcomes.
  - Causal ML, DML, honest tree, matrix completion, etc.

Empirical policy research often focuses on causal inference. Since policy choices seem to depend on understanding the counterfactual—what happens with and without a policy—this tight link of causality and policy seems natural. While this link holds in many cases, we argue that there are also many policy applications where causal inference is not central, or even necessary.

Abstract. Product and content personalization is now ubiquitous in e-commerce. There are typically not enough available transactional data for this task. As such, companies today seek to use a variety of information on the interactions between a product and a customer to drive personalization decisions. We formalize this problem as one of recovering a large-scale matrix with side information in the form of additional matrices of conforming di-mension. Viewing the matrix we seek to recover and the side information we have as sikes of a tensor, we consider the problem of sike recovery, which is to recover specific silces of simple' tensors from noisy observations of the entire tensor. We propose a definition of simplicity that on the one hand elegantly generalizes a standard generative model for our motivating problem and on the other hand subsumes low-rank tensors for a variety of existing definitions of tensor rank. We provide an efficient algorithm for sike recovery that is practical for massive data sets and provides as significant performance improvement over state-of-the-art incumbent approaches to tensor recovery. Furthermore, we establish near-optimal recovery guarantees that, in an important regime, represent an order improvement over the best available results for this problem. Experiments on data from a music streaming service demonstrate the performance and scalability of our algorithm.

Searn, C. J. S. A. ging paragagacran easy (remeasegagacran east) enhances a laborative filtering (CF) algorithms to recommend products to consumers. What recommendations consumers receive and how they respond to the recommendations largely depend on the design of CF algorithms. However, the extant empirical research on recommender systems has primarily focused on how the presence of recommendations effects produce demand, without considering the underlying algorithm design. Leveraging a field experiment on a major e-commerce platform, we examine the differential impact of the widely used CF essigns: view-abox-view (VAI) and purchase-also-purchase (FAP). We found several striking differences between the impact of these two designs on individual products. First, VAI' is about seven times more effective in mercating the views from PaP but only about twice as effective in generating additional products. This value is about views from one expensive products, whereas PaP is more effective in increasing the scales of release products with higher precise in increasing the views but more effective in increasing the sales of cheaper products with the same levels of price or PRs, VAI' dominates PAP in generating view and the difference in the constraint of the products with the same levels of price or PRs, VAI' dominates PAP in generating view and the different in the products with the same levels of price or PRs, VAI' dominates PAP in generating view of the products with the same levels of price or PRs, VAI' dominates PAP in generating view of the products with the same levels of price or PRs, VAI' dominates PAP in generating view of the products with the same levels of price or PRs, VAI' dominates PAP in generating view of the price of PRs, VAI' dominates PAP in generating view of the products view of the price of PRs, VAI' dominates VAI' generates more sales than PAP overall. Our fluidings taggest that platforms may benefit from employing different CF designs for different types of products.

It has become increasingly important given the ever-growing popularity of or videos. However, prediction of watch time not only depends on the match between the user and the recommendation is always biased towards videos with long duration. Models trained on this videos with long duration but overlook the underlying user interests. This paper presents the first work illuminating that duration is a confounding factor that concurrently affects video exposure and watch second effect on watch time originates from video intrinsic characteristics and should be preserved. To remove the undesired bias but leverage the natural effect, we propose a Duration-Deconfounded Quantile-based (D2Q) watch-time prediction framework, which allows for scalability to perform or activeness of this duration-deconfounding framework by significantly outperforming the state-o the-art baselines. We have fully launched our approach on Kuaishou App, which has substantially

We perform a comparative analysis of machine learning methods for the canonical problem of empirical asset pricing: measuring asset risk premiums. We demonstrate large economic gains to investors using machine learning forecasts, in some cases doubling the performance of leading regression-based strategies from the literature. We identify the best-performing methods (trees and neural networks) and trace their predictive gains to allowing nonlinear predictor interactions missed by other methods. All methods agree on the same set of dominant predictive signals, a set that includes variations on momentum, liquidity, and volatility. (JEL C52, C55, C58, G0, G1, G17)

Pancreatic ductal adenocarcinoma (PDAC), the most deadly solid malignancy, is typically detected late and at an inoperable stage. Early or incidental detection is associated with prolonged survival, but screening asymptomatic individuals for PDAC using a single test remains unfeasible due to the low prevalence and potential harms of false positives. One-contrast computed tomography (CT), routinely performed for clinical indications, offers the potential for large-scale screening, however, identification of PDAC using non-contrast CT has long been considered impossible. Here, we develop a deep learning approach, pancreatic cancer detection with artificial intelligence (PANDA), that can detect and classify pancreatic lesions with high accuracy via non-contrast CT. PANDA is trained and adasset of 3.20 patients from a single center. PANDA achieves an area pancreatclesions with high accuracy via non-contrast CT. PANDA steriand on adiaset of 3.20 Battents from a single center, PANDA achieves an area under the receiver operating characteristic curve (AUC) of 0.986-0.996 for lesion detection in a multicenter validation involving o.239 patients across 10 centers, outper forms the mean radiologist performance by 3-4.18 in sensitivity and 6.38 in specificity of PDAC Identification, and achieves a sensitivity of 92-98 and specificity of 999% for lesion detection in a real-world multi-scenario validation consisting of 20.530 consecutive patients. Notably, PANDA utilized withom-contrast CT shows non-inferiority to radiology reports (using contrast-enhanced CT) in the differentiation of common pancreatic lesion subtypes. PANDA could potentially serve as a new tool for large-scale pancreatic cancer screening.

Abstract

Can machine learning improve human decision making? Bail decisions provide a good test case. Millions of times each year, judges make jail-or-release decisions that hinge on a prediction of what a defendant would do if released. The concreteness of the prediction task combined with the volume of data available makes this a promising machine-learning application. Yet comparing the algorithm to judges proves complicated. First, the available data are generated by prior judge decisions. We only observe crime outcomes for released defendants, not for those judges detained. This makes it hard to evaluate counterfactual decision rules based on algorithmic predictions. Second, judges may have a broader set of preferences than the variable the algorithm predicts; for instance, judges may care specifically about violent crimes or about racial inequities. We deal with these problems using different econometric strategies, such as quasi-random assignment of cases to judges. Even accounting for these concerns, our results suggest potentially large welfare gains: one policy simulation shows crime reductions up to 24.7% with no change in jailing rates, or jailing rate reductions up to 41.9% with no change in jailing rates, or jailing rate reductions up to 41.9% with no change in jailing rates, or jailing rate reductions up to 41.9% with no change in jailing rates, or jailing rate reductions up to 41.9% with no change is jailing rates, or jailing rate reductions up to 41.9% with no change is jailing rates, or jailing rate reductions up to 41.9% with no change is jailing rates. Presently suggest that while machine learning can be valuable, realizing this value requires integrating these tools into an economic framework being clear about the link between predictions and decisions; specifying the scope of payoff functions; and constructing unbiased decision counterfactuals.

Partition of New York City Data (2008–13) into Data Sets Used for Prediction and Evaluation

# When Do Predictions Make No Sense?

- You are not predicting sufficiently important macro economic/political/natural outcomes.
- · Your prediction is neither accurate nor causal for decision-making.

$$\frac{d\pi(X_0, Y)}{dX_0} = \frac{\partial \pi}{\partial X_0} \underbrace{(Y)}_{\text{prediction}} + \underbrace{\frac{\partial \pi}{\partial Y}}_{\text{causation}} \underbrace{\frac{\partial Y}{\partial X_0}}_{\text{causation}}.$$

Your prediction of Y is not accurate.

9

Your causal identification is not clean.

• Your predictions of the counterfactual outcomes are ungrounded because of the violation of unconfoundedness (a.k.a. CIA) and/or common support (a.k.a. overlapping condition) assumptions.
